

**Microeconomics for Management - Yossi Spiegel**

**Problem set 8**

Problem 1

A firm produces its output using a single input. The production function is given by  $q = bx^\alpha$ , where  $q$  denotes the output,  $x$  denotes the quantity of the input, and  $b$  and  $\alpha$  are positive constants. The per-unit cost of the input is  $w$ .

- (a) Derive the cost function of the firm and use it to compute the marginal and average costs.
- (b) Illustrate the production function, cost function, and marginal and average cost functions in three separate graphs. Make sure you distinguish between the case where  $\alpha < 0$ ,  $\alpha = 1$ , and  $\alpha > 1$ .
- (c) Repeat your answer to (b) under the assumption that the production function is given by  $q = 0$  if  $x < x_0$ , and  $q = b(x-x_0)^\alpha$  if  $x \geq x_0$ , where  $x_0$  is some positive constant. Explain in words the meaning of  $x_0$  and explain how it affects the marginal and average cost functions and why.

Problem 2

Consider a perfectly competitive industry with 16 identical firms, each of which has a cost function  $c(q) = F + q^2$ , where  $F$  is a positive constant. The demand function in this industry is  $Q = A/p$ , where  $A$  is a positive constant.

- (a) Compute the short-run competitive equilibrium in this industry.
- (b) How do changes in  $A$  and  $F$  affect the equilibrium? Explain the intuition for your answer.
- (c) For which values of  $A$  and  $F$  do firms earn positive profits, negative profits, and 0 profits?
